Objective To characterize influenza seasonality and identify the best time of the year for vaccination against influenza in tropical and subtropical countries of southern and south-eastern Asia that lie north of the equator.

Methods Weekly influenza surveillance data for 2006 to 2011 were obtained from Bangladesh, Cambodia, India, Indonesia, the Lao People's Democratic Republic, Malaysia, the Philippines, Singapore, Thailand and Viet Nam. Weekly rates of influenza activity were based on the percentage of all nasopharyngeal samples collected during the year that tested positive for influenza virus or viral nucleic acid on any given week. Monthly positivity rates were then calculated to define annual peaks of influenza activity in each country and across countries.

Findings Influenza activity peaked between June/July and October in seven countries, three of which showed a second peak in December to February. Countries closer to the equator had year-round circulation without discrete peaks. Viral types and subtypes varied from year to year but not across countries in a given year. The cumulative proportion of specimens that tested positive from June to November was > 60% in Bangladesh, Cambodia, India, the Lao People's Democratic Republic, the Philippines, Thailand and Viet Nam. Thus, these tropical and subtropical countries exhibited earlier influenza activity peaks than temperate climate countries north of the equator.

Conclusion Most southern and south-eastern Asian countries lying north of the equator should consider vaccinating against influenza from April to June; countries near the equator without a distinct peak in influenza activity can base vaccination timing on local factors.

Abstracts in عربي, Français, Русский and Español at the end of each article.

Introduction

Influenza is a vaccine-preventable disease; safe and effective vaccines have been used for more than 60 years to mitigate the impact of seasonal epidemics.1 Annual human influenza epidemics occur during the respective winter seasons in the temperate zones of the northern and southern hemispheres – i.e. between November and March in the northern hemisphere and between April and September in the southern hemisphere.1,3 Data on influenza strains circulating globally are used to predict which strains have the highest probability of circulating in the subsequent season and this information is used to generate recommendations for seasonal influenza vaccine composition.4 The effectiveness of influenza vaccines depends not only on the right match between vaccine strains and circulating viral...
strains, but also on the vaccine-induced immune response in the target population. Several types of influenza vaccine are regularly available on the market. The most commonly used one – non-adjuvanted, influenza-virus-containing vaccine (the “inactivated influenza vaccine”) – induces neutralizing antibody responses that wane during the year. Therefore, appropriate timing of vaccination is a very important consideration in efforts to improve vaccine effectiveness. Better understanding of influenza seasonality and viral circulation is essential to selecting the best time for vaccination campaigns, which should precede the onset of the influenza season by several weeks.

Despite substantial influenza-associated morbidity and mortality and increasing local vaccine manufacturing capacity, many tropical Asian countries have yet to improve population-wide routine influenza vaccination. Although influenza surveillance data have been very useful in developing vaccination strategies in temperate regions, fewer data are available from countries in tropical and subtropical areas. Current progress in influenza surveillance and the widespread use of highly sensitive molecular assays for influenza diagnosis and viral typing have shown more complicated patterns of influenza activity in the tropics and subtropics than in other areas, with year-round circulation in some regions and biannual peaks of circulation in others. Such undefined patterns of influenza activity further complicate vaccination recommendations and, in particular, the selection of an appropriate time for vaccination. We undertook the analysis of influenza surveillance data from 10 countries in tropical and subtropical parts of southern and south-eastern Asia to characterize common trends in influenza circulation and therefore identify the most appropriate time for vaccination.

Methods

Data collection

Nasopharyngeal swabs from patients presenting with influenza-like-illness were collected at various clinics within each country as part of an influenza surveillance network across the Asian region. The number of specimens tested and the number of samples positive for influenza virus or viral nucleic acid were collected directly from weekly surveillance data or extracted from FluNet for 10 selected countries in Asia: Bangladesh, Cambodia, India, Indonesia, the Lao People’s Democratic Republic, Malaysia, the Philippines, Singapore, Thailand and Viet Nam. FluNet data are regularly collected by surveillance systems in geographically disparate sentinel sites that register cases of influenza-like illness or severe acute respiratory infection. Data on specimen positivity and on viral subtypes were based upon specimens from these surveillance systems; all samples were tested using reverse transcription polymerase chain reaction assays, with the exception of samples from India collected before 2009, which were tested with viral isolation methods.

Since influenza surveillance in the different countries was started in different years, data for India, Malaysia, the Philippines and Viet Nam were available for 2006 to 2011; data for Cambodia, Indonesia, Singapore and Thailand, for 2007 to 2011; and data for Bangladesh and the Lao People’s Democratic Republic, for 2008 to 2011.

Data analysis

Data on laboratory-confirmed influenza for each country were analysed individually in MS Excel (Microsoft, Redmond, United States of America) and PASW Statistics 18 (SPSS Inc., Chicago, USA). Monthly influenza activity was calculated by adding the weekly number of specimens that tested positive during a given month. The monthly data were then plotted as the percentage of all positive specimens during the calendar year that corresponded to that month. Means and standard errors were calculated from the cumulative data for each country over the period evaluated. Data from 2009 were processed separately owing to the emergence of influenza virus A(H1N1)pdm09, which did not follow the usual seasonal pattern of influenza viruses.

Results

Circulating influenza viruses

Of a total of 253 611 specimens tested in the 10 participating countries, 45 282 (17.9%) were positive for viral nucleic acid (or for influenza viruses from specimens from India obtained before 2009) (Table 1).

Bangladesh

Of the 12 583 specimens tested between 2008 and 2011, 1747 (13.9%) were positive (Table 1). Analysis of monthly data showed that influenza activity was highest from June to September during most years (Fig. 1 and Fig. 2), with peak activity in July and August (Fig. 2). Subtype A H1 and type B influenza viruses were the ones most frequently reported during 2008 (Fig. 3): they were found in 39.3% and 46.7%, respectively, of all specimens that tested positive. Influenza A(H1N1)pdm09 emerged in mid-2009 (42.7%) and its circulation persisted in 2010 (39.2%); it co-circulated mainly with subtype A H3 viruses (51.1%) in 2009 and with type B viruses (43.6%) in 2010 (Fig. 3). A H3 viruses were the ones most frequently reported in 2011 – 50.4% of all positive specimens – followed by type B viral strains (47.1%) (Fig. 3).

Cambodia

Of the 10 105 specimens tested from 2007 to 2011, 1574 (15.6%) were positive (Table 1). Analysis of monthly data showed influenza activity primarily from July to December for most years (Fig. 1 and Fig. 2), with discrete peaks in September to October (Fig. 2). In 2007, influenza activity peaked in March and in August to September, while a peak of activity was identified between September and November for 2008 and between August and November for 2010 and 2011 (Fig. 1). Subtype A H3 (29.5% and 53.7%) and type B (56.8% and 34.1%) viral strains were the ones most frequently reported in 2007 and 2008. Influenza A(H1N1)pdm09 virus (22.9%) emerged in mid-2009 and its circulation persisted in 2010 (32.8%) and 2011 (25.2%), with co-circulation of subtype A H3 viruses (53.1%, 40.2%, and 9.2% in 2009, 2010 and 2011, respectively) and type B viral strains (22.9%, 27.0% and 65.6% in 2009, 2010 and 2011, respectively) (Fig. 3).

India

Of the 28 024 specimens tested from 2006 to 2011, 2803 (10.0%) were positive (Table 1). Between 2006 and 2008 all samples were studied by virus isolation methods. Analysis of monthly data showed increased influenza activity after June for most years (Fig. 1 and Fig. 2), with discrete peaks between June and August (Fig. 1). In 2008, influenza activity remained above background activity throughout the
year (Fig. 1). India had highly divergent monthly patterns between the northern and the southern states (data not shown). Subtype A H1 and type B viruses were the most frequently reported in 2006 and 2007 (35.0% and 38.0% for subtype A H1, and 38.5% and 47.0% for type B viruses, respectively), A H1, and 38.5% and 47.0% for type B viruses, respectively, and 320 and 320 for subtype A H3 virus and 49.9% and 45.5% for type B virus, respectively). Identification of A(H1N1)pdm09 in the country varied from 11.8% of positive specimens in 2010 to 29.0% in 2011 (Fig. 3; no virus identification data were available for 2009).

**Indonesia**

Of the 15,150 specimens tested from 2007 to 2011, 2,902 (16.6%) were positive (Table 1). Analysis of monthly data showed year-round influenza activity for most years and different months of peak influenza activity in some years (Fig. 1 and Fig. 2). Circulating influenza types and subtypes were available only for 2010 and 2011. Influenza subtype A H3 and type B viruses were the most frequently reported (37.1% and 45.5%, for subtype A H3 virus and 49.9% and 24.8% for type B viruses, respectively). Of the 15,150 specimens tested from 2007 to 2011, 2,902 (16.6%) were positive (Table 1). Analysis of monthly data showed year-round influenza activity for most years and different months of peak influenza activity in some years (Fig. 1 and Fig. 2). Circulating influenza types and subtypes were available only for 2010 and 2011. Influenza subtype A H3 and type B viruses were the most frequently reported (37.1% and 45.5%, for subtype A H3 virus and 49.9% and 24.8% for type B viruses, respectively). Identification of A(H1N1)pdm09 in the country varied from 11.8% of positive specimens in 2010 to 29.0% in 2011 (Fig. 3; no virus identification data were available for 2009).

**Laos People’s Democratic Republic**

Of the 5,949 specimens tested from 2008 to 2011, 1,302 (21.9%) were positive (Table 1). Analysis of monthly data showed influenza circulation primarily from August to December for most years (Fig. 1),

- Singapore (Singapore: 1.3° N)

Proposed best time for vaccination

(continues ...)
with discrete peaks in August, September and October (Fig. 1 and Fig. 2). The Lao People’s Democratic Republic reported circulation of subtype A H1 and type B viruses in 2008 (43.5% and 56.5%, respectively). Influenza A(H1N1)pdm09 virus emerged in mid-2009 (47.5%) and persisted in 2010 (56.1%). Type B viruses were also identified in the country in 2010 (31.0%) and 2011 (31.3%). In 2011, A H3 was the most frequently reported viral subtype (63.5% of positive specimens) (Fig. 3).

**Malaysia**

Of the 10,323 specimens tested from 2006 to 2011, 894 (8.7%) were positive (Table 1). Analysis of monthly data showed year-round influenza activity for most years and different months of peak influenza activity in different years (Fig. 1 and Fig. 2). Influenza A H1, A H3 and type B viruses circulated at varying levels in 2006 to 2008 (14.0–65.2%), while A(H1N1)pdm09 virus (24.5%) emerged in mid-2009 and persisted in 2010 (56.3%); it co-circulated with subtype A H3 (52.3%) and type B viruses (21.8%) in 2009 and mainly with type B viruses (39.6%) in 2010 (Fig. 3).

**The Philippines**

Of the 69,108 specimens tested from 2006 to 2011, 12,607 (18.2%) were positive (Table 1). Analysis of monthly data showed influenza activity primarily from June to October (Fig. 1 and Fig. 2), with discrete peaks in July, August and September (Fig. 2). Subtype A H1 (46.1%) and type B strains (44.0%) were the predominant viruses in 2006; A H1 and A H3 viral subtypes were the ones most frequently reported in 2007 (34.1% and 59.7%, respectively), as were type B strains in 2008 (75.7%). Influenza A(H1N1)pdm09 virus (92.8%) emerged in mid-2009 and persisted in 2010 (33.4%), when it co-circulated with type B (50.1%) and subtype A H3 viruses (16.4%). Influenza A(H1N1)pdm09 was the virus most frequently (53.2%) reported in 2011, followed by type B influenza viruses (31.8%) (Fig. 3).

**Singapore**

Of the 55,449 specimens tested from 2007 to 2011, 12,801 (23.1%) were positive (Table 1). Analysis of monthly data showed year-round influenza activity and different months of peak influenza activity in different years (Fig. 1 and Fig. 2). Type B viruses were the most frequently reported influenza viruses in 2007 (79.1%) and 2008 (45.7%). Influenza A(H1N1)pdm09 (79.2%) emerged in mid-2009 and persisted in 2010 (55.8%) and 2011 (44.2%); it co-circulated with subtype A H3 (22.5% and 33.8%, respectively) and type B viruses (21.7% and 22.0% respectively; Fig. 3).

**Thailand**

Of the 17,421 specimens tested from 2007 to 2011, 3802 (21.8%) were positive (Table 1). Analysis of monthly data showed that increased influenza activity occurred from January to March and from June to November or December on some years (Fig. 1 and Fig. 2), with discrete peaks in August to September (Fig. 2). Subtype A H1 (46.1%) and type B strains (44.0%) were the predominant viruses in 2006; A H1 and A H3 viral subtypes were the ones most frequently reported in 2007 (34.1% and 59.7%, respectively), as were type B strains in 2008 (75.7%). Influenza A(H1N1)pdm09 virus (92.8%) emerged in mid-2009 and persisted in 2010 (33.4%), when it co-circulated with type B (50.1%) and subtype A H3 viruses (16.4%). Influenza A(H1N1)pdm09 was the virus most frequently (53.2%) reported in 2011, followed by type B influenza viruses (31.8%) (Fig. 3).

**Viet Nam**

Of the 29,499 specimens tested from 2006 to 2011, 5,241 (17.8%) were positive (Table 1). Analysis of monthly data showed year-round circulation (Fig. 1 and Fig. 2), and some peak activity in July to August (Fig. 2). Subtype A H1 and type B viruses were the most frequently reported in 2006 and 2008, at 43.5 to 53.7% and 40.8 to 41.3%, respectively, whereas A H3 subtype (73.9%) and type B viruses (25.1%) were the ones most frequently reported in 2007. Influenza A(H1N1)pdm09 emerged (46.6%) in mid-2009 and persisted in 2010 (28.0%), when it co-circulated with subtype A H3 (71.5%) viruses. In 2011, A(H1N1)pdm09 was the influenza virus most frequently reported (74.1%), followed by type B viruses (22.1%, Fig. 3).

Dec, December; Jun, June; Nov, November.
a Proportion of specimens that tested positive for influenza virus or viral nucleic acid. Data for 2009 are excluded.
b Data from local clinics, private or public, not necessarily adherent to the country’s Ministry of Health guidelines.
c Hajj is the largest annual human gathering in the world and vaccination is important to protect from widespread influenza transmission. Hajj dates vary from year to year (July–December) since they depend on the moon.
d The northern most states of Jammu and Kashmir in India have peaks of influenza circulation in December to March and should consider vaccination in October to November (Mandeep Chadha, personal communication).
e In 2012, with donated northern hemisphere influenza vaccine formulation.
f Vaccine delivery may be dictated by opportunity, such as annual health screening events or health-care encounters.
g Singapore had a high positivity rate in January 2011. This skewed the proportions towards higher values in December to May.

Circulating influenza types and subtypes

Different types and subtypes of influenza viruses circulated across southern and south-eastern Asia during the years studied: type A (subtypes H1 and H3) and type B strains (Fig. 3). Influenza A H1, A H3 and type B viruses were reported across the countries in 2006, 2007 and 2008. As in the rest of the world, pandemic A(H1N1)pdm09 appeared in southern and south-eastern Asia in 2009; it was detected at different times in the various countries and it co-circulated with other influenza viruses (Fig. 1 and Fig. 3). In 2009, A(H1N1)pdm09 and subtype A H3 (plus some subtype A H1 and type B viruses) co-circulated in Bangladesh, Cambodia, India, the Lao People’s Democratic Republic, Thailand and Viet Nam, whereas A(H1N1)pdm09 was the predominant subtype reported from the Philippines and Singapore in 2009. In 2010, A(H1N1)pdm09 co-circulated mainly with type B viruses in some countries (Bangladesh, India, the Lao People’s Democratic Republic, Malaysia, the Philippines and Thailand), and with subtype A H3 viruses in others (Cambodia and Viet Nam). In 2011, some countries (Bangladesh, India, the Lao People’s Democratic Republic and Thailand) showed almost no circulation of A(H1N1)pdm09 and varying degrees of co-circulation of subtype A H3 and type B viruses, while others (Cambodia, Indonesia, the Philippines, Singapore and Viet Nam) continued to have co-circulation of A(H1N1)pdm09 and influenza B (Fig. 3).

Influenza circulation and vaccination timing

Two major patterns of influenza circulation emerged from this study (Fig. 2). Some countries (Bangladesh, Cambodia, India, the Lao People’s Democratic Republic, the Philippines, Thailand and Viet Nam) presented influenza peak activity between June and October, and three of them (India, Thailand and Viet Nam) showed additional minor peak activity during the northern hemisphere winter. Other countries (Indonesia, Malaysia and Singapore) had year-round influenza activity and variable peak activity in some years (Fig. 4).

Cumulative analysis of monthly influenza activity between 2006 and 2011 in the 10 countries revealed that > 60% of influenza cases were reported in June to November for Bangladesh, Cambodia, India, the Lao People’s Democratic Republic, the Philippines, Thailand and Viet Nam (Table 2), whereas countries closer to the equator (Indonesia, Malaysia and Singapore) had similar circulation of influenza viruses in both semesters (Table 2). The best vaccination times for each country, as proposed, are indicated by an arrow in Fig. 2.

Discussion

Weekly influenza surveillance data collected between 2006–2008 and 2011 were analysed for 10 countries in tropical and subtropical southern and south-eastern Asia. Despite differences in surveillance methods, demographic characteristics and environmental factors, it was possible to show peaks of influenza circulation in some countries, while in others influenza activity was detected throughout the year. These findings are consistent with the reports from the countries. Host-related and environmental factors (e.g. lower temperatures and decreased humidity) may influence both viral transmission and host susceptibility.

Several countries, such as Bangladesh, Brazil, India and Viet Nam, have reported high influenza activity that coincides with rainy seasons, while other countries, such as the Philippines, Singapore and Thailand, have reported semi-annual
peaks that are not necessarily associated with rainfall. Thus, the seasonality of influenza in the tropics and subtropics appears to be country-specific. Throughout the surveillance period, influenza virus types A and B co-circulated across all countries included in this study. In 2009, influenza A(H1N1)pdm09 virus appeared in the area and persisted, with limited circulation, in 2010 and 2011. Some other countries also continued to report A(H1N1)pdm09 in 2011, and again during the winter of 2012. In 2011, A H3 virus was the subtype most frequently reported in several countries (Bangladesh, India, the Lao People’s Democratic Republic and Thailand). This resurgence of subtype A H3, explained as an antigenic drift of the virus, has led to the selection of A H3 Victoria for the vaccine formulation for the northern hemisphere in 2012–2013.

During the study period, we observed that most countries in tropical and subtropical southern and south-eastern Asia (Bangladesh, Cambodia, India, the Lao People’s Democratic Republic, the Philippines and Thailand) experienced peak influenza activity between June/July and October, ahead of most counties in the northern hemisphere, where influenza vaccine formulations are usually available around October (Fig. 4). Since country-specific data on influenza seasonality for most tropical and subtropical countries are sparse, vaccine licensing and use, and the timing of vaccination campaigns, have been historically regulated in accordance with their hemispheric location. Nevertheless, as influenza vaccination should precede peak activity periods in order to confer maximum protection, tropical and subtropical countries should consider starting vaccination campaigns earlier than other countries in the same hemisphere; i.e. during April to June each year for countries of southern and south-eastern Asia (Fig. 2). This is consistent with reports from Brazil stressing that the designation of influenza seasons by hemisphere may not apply to tropical and subtropical countries.

There is no ideal vaccine timing for equatorial countries with year-round influenza activity and without defined peaks of disease activity, such as Indonesia, Malaysia and Singapore. For these countries, the best recommendation would be to use the most recent vaccine formulation recommended by the World Health Organization (WHO) in that year. In Singapore, the Ministry of Health issues advisories once or twice a year when new vaccines with a change in formulation are released; since vaccines are purchased at an institutional level, residents usually receive the most recent influenza vaccine in their regular medical visits (Raymond Lin, personal communication). For countries that cover large areas with different average temperatures, an advisable option would be to use subnational data to guide sequential vaccine purchases and to select the time for vaccination campaigns. As an example, surveillance data in Indonesia show seasonal peaks of influenza in December and January for most of the islands, while other islands have peaks of infection from May to July. Similarly, countries with a large latitudinal span, like India, may also benefit from using subnational surveillance data to identify locally appropriate vaccination times. A summary of current and proposed influenza vaccination timing is shown in Table 2.

Although decades of public health research and global experience have shown that vaccination against influenza confers the best protection against influenza-associated deaths and complications, influenza vaccines are not available as part of routine public health programmes in most low- and middle-income countries in Asia. Nevertheless, the recent pandemic alarm in 2009, plus ongoing outbreaks of emerging influenza strains in other countries, such as A(H5N1) and, most recently, A(H7N9), as well as the number of deaths and complications in some regular influenza seasons, have increased the interest in influenza control in the area. To address the growing need for more affordable and accessible influenza vaccines during a pandemic, WHO has assisted countries in Asia (India, Indonesia, Thailand and Viet Nam) in developing their domestic vaccine production capacity. As a result, many countries have already established influenza vaccine manufacturing capabilities and some used locally produced vaccines during the 2009 pandemic. Furthermore, a recent pilot programme of influenza vaccination in the Lao People’s Democratic Republic demonstrated that public–private partnerships can improve vaccination programmes in developing countries.

The data reported here have limitations. The surveillance data collected in the countries during the six-year period only allow analyses of trends based on the percentages of nasopharyngeal specimens that tested positive, but not the calculation of incidence rates. In addition, comparison between the countries is difficult because of differences between countries in surveillance procedures and/or data collection methods (i.e. different sampling strategies, case definitions, age group selection, outpatient versus inpatient selection and biological tests), as well as in the criteria for submitting data to FluNet. Furthermore, the reporting systems might have changed over time, especially after 2009; different countries started surveillance at different times and some expanded or changed their surveillance sites over the study period. Nevertheless, these data provide a good overview of influenza seasonality and peaks of influenza circulation over the years; therefore, we were able to discern yearly trends for influenza circulation in each country, which revealed consistent patterns applicable to several tropical and subtropical countries in Asia.

In summary, we identified some patterns of circulation of influenza viruses in 10 tropical and subtropical Asian countries that are different from the patterns commonly seen in temperate countries. An early peak of influenza activity was detected between June and October, followed in some countries by a second, winter peak in December to February. Countries located close to the equator exhibited year-round circulation of the virus. Consequently, vaccination campaigns should adapt to the natural history of the virus in each country – i.e. vaccination campaigns should start before vaccination in countries of the temperate northern hemisphere showing early peaks of infection. On the other hand, for countries without epidemic peaks, year round vaccination with updated licensed vaccines might be required. These data can help decision-makers to better target vaccination programmes and inform regulatory authorities regarding the licensing of vaccines best timed to prevent seasonal epidemics in their country.

Research
Influenza seasonality and vaccination timing in south-eastern Asia

Siddhartha Saha et al.

Abstract
South Asia and Southeast Asia tropical and subtropical regions influenza seasonality and vaccine timing

Objective
Characterise the influenza seasonality and identify the better time of the year for influenza vaccination in the tropical and subtropical areas of South Asia and Southeast Asia.

Methods
The weekly influenza surveillance data are obtained from Bangladesh, Cambodia, India, Indonesia, Laos, Malaysia, Philippines, Singapore, Thailand and Vietnam. The weekly influenza activity rates are based on the percentage of all nasopharyngeal samples collected in a year that tested positive for influenza virus or viral nucleic acid in a given week. Then, the monthly positive rates are calculated to determine the annual influenza activity peaks at the national and international levels.

Results
Influenza activity reached its peak between June/July and October in seven countries, among which three countries experienced a second peak between December and February. Countries close to the equator experience year-round transmission without distinct peaks. The virus types and subtypes vary from year to year, but not between countries in a given year. The cumulative percentage of positive samples from June to November was greater than 60% in Bangladesh, Cambodia, India, Laos, Philippines, Thailand and Vietnam. Therefore, these tropical and subtropical countries have experienced earlier influenza activity peaks than the temperate countries located in the north of the equator.

Conclusion
The majority of the countries in South and Southeast Asia north of the equator should consider influenza vaccination from April to June. Countries close to the equator without distinct influenza activity peaks can determine their vaccination schedule based on local factors.
Сезонность гриппа и сроки вакцинации в тропических и субтропических районах Южной и Юго-Восточной Азии

Цель. Охарактеризовать сезонность гриппа и определить лучшее время года для проведения вакцинации против гриппа в тропических и субтропических странах Южной и Юго-Восточной Азии, расположенных к северу от экватора.

Методы. Ежегодные данные эпидемиолога по гриппу с 2006 по 2011 гг. были получены из Бангладеш, Камбоджи, Индии, Индонезии, Лаосской Народно-Демократической Республики, Малайзии, Филиппин, Сингапура, Таиланда и Вьетнами. Недельные показатели активности гриппа вычислялись на основе процента от общего количества всех мазков из носоглотки, собранных в течение года, показавших положительный результат на вирус гриппа или вирусную нуклеовирозную кислоту в течение любой данной недели. Затем были рассчитаны месячные показатели позитивности с целью определить ежегодные пики активности гриппа в каждой из стран и во всех странах региона.

Результаты. Активность гриппа достигала своего пика между июнем/июлем и октябрем в семи странах, в трех из которых отмечен второй пик с декабря по февраль. Страны ближе к экватору имели круглогодичную циркуляцию заболевания без отдельных пиков. Вирусные типы и подтипы менялись из года в год, но не во всех странах в отдельно взятом году. Совокупная доля положительных образцов с июня по ноябрь составила > 60% в Бангладеш, Камбодже, Индии, Лаосской Народно-Демократической Республике, Филиппинах, Таиланде и Вьетнаме. Таким образом, эти тропические и субтропические страны показали более ранние пики активности гриппа по сравнению со странами с умеренным климатом к северу от экватора.

Вывод. Большинству стран Южной и Юго-Восточной Азии, расположенных к северу от экватора, следует рассмотреть проведение вакцинации против гриппа в сроки с апреля по июнь; страны ближе экватора без четко выраженного пика активности гриппа могут определять сроки вакцинации исходя из местных факторов.

Resumen

La estacionalidad de la gripe y la fecha de vacunación en áreas tropicales y sub tropicales del sur y sureste de Asia

Objetivo. Describir la estacionalidad de la gripe e identificar el mejor momento del año para llevar a cabo la vacunación contra la gripe en países tropicales y sub tropicales del sur y sureste de Asia situados al norte del ecuador.

Métodos. Se obtuvieron los datos semanales de vigilancia de la gripe de los años 2006 a 2011 de Bangladesh, Camboya, India, Indonesia, la República Democrática Popular Lao, Malasia, Filipinas, Singapur, Tailandia y Viet Nam. Las tasas semanales de la actividad de la gripe se basaron en el porcentaje de todas las muestras nasofaríngeas recogidas durante el año que dieron positivo en la prueba del virus de la gripe o del ácido nucleico en cada uno de los países y entre países.

Resultados. La actividad de la gripe experimentó un aumento entre junio y julio, y octubre en siete países, tres de los cuales mostraron un segundo pico de actividad de diciembre a febrero. Los países más cercanos al ecuador presentaron una circulación durante todo el año sin picos discontinuos. Los tipos y subtipos virales variaron de año en año, pero no entre los países en un año determinado. La proporción acumulada de individuos que dieron positivo de junio a noviembre fue > 60% en Bangladesh, Camboya, India, la República Democrática Popular Lao, Filipinas, Tailandia y Viet Nam. Así, en estos países tropicales y sub tropicales, los picos de actividad de la gripe se produjeron antes que en los países de clima templado al norte de la línea ecuatorial.

Conclusión. La mayoría de los países del sur y sureste asiático situados al norte del ecuador deberían considerar llevar a cabo la vacunación contra la gripe de abril a junio, mientras que los países cercanos al ecuador sin picos marcados en la actividad de la gripe pueden basar la fecha de vacunación en factores locales.
