
ABSTRACT

OBJECTIVE: To describe changes in prevalence of child undernutrition in Northeastern Brazil in two successive time periods, identifying, in each period, the major factors responsible for these changes.

METHODS: Data analyzed are from probabilistic samples of underfives from three Demographic Health Surveys carried out in 1986 (n=1,302), 1996 (n=1,108), and 2006 (n=950). Identification of factors responsible for temporal changes in child undernutrition (height-for-age below < -2 z) took into account time changes in five potential determinants of child nutritional status, statistical modeling of the independent association between determinants and risk of undernutrition, and calculation of attributable fractions.

RESULTS: Prevalence of child undernutrition fell by one-third between 1986 and 1996 (from 33.9% to 22.2%) and by almost three-quarters between 1996 and 2006 (from 22.2% to 5.9%). Improvements in maternal schooling and in the coverage of water and sewage services were particularly important for the decline in child undernutrition in the first period, while increasing purchasing power of the poorest families and, again, maternal schooling were more relevant in the second period.

CONCLUSIONS: The acceleration of the decline in child undernutrition between the two periods was consistent with accelerated improvement of maternal schooling, water supply and sewage, health care, and maternal reproductive antecedents, as well as with the outstanding increase in purchasing power among the poorest families and, again, maternal schooling were more relevant in the second period.

INTRODUCTION

Childhood undernutrition, as diagnosed by growth deficits, is one of the most important health problems faced by developing countries. It is associated with higher risk of infectious disease and early mortality, impaired psychomotor development, lower academic achievement, and lower reproductive capacity in adulthood. Reducing prevalence of anthropometric deficits in underfives by half is one of the Millennium Development Goals established by the United Nations in the year 2000.

Anthropometric surveys based on probabilistic samples of the Brazilian underfive population carried out in the 1970's, 1980's, and 1990's showed a systematic concentration of undernutrition in the country's Northeast Region. In 1974/75, the National Family Budget Survey showed that stunting (height-for-age deficit) was two times more frequent in the Northeast than in the Center-West, Southeast, and South Regions (Center-South). In 1989, the National Survey of Health and Nutrition, despite reporting a reduction in undernutrition in all of the country's regions, showed that such decline was relatively less intense in the Northeast, making the prevalence of stunting three times higher in that region than in the Center-South. In 1996, the Demographic Health Surveys (DHS) program indicated a further decline in undernutrition, which this time was equivalent in the Northeast and Center-South, maintaining the three-fold difference in risk of stunting between these regions.

An initial analysis of the data from the most recent Brazilian DHS survey, carried out in 2006/07, ratified the declining trend in infant undernutrition across all Regions, but this time showing a particularly intense reduction in height-for-age deficit in the Northeast. This reduction virtually eliminated the disadvantage of this Region with respect to the rest of the country.

The aim of the present study was to describe the temporal variation in prevalence of child undernutrition in the Northeast Region of Brazil across two periods (1986-1996 and 1996-2006) and to identify major factors contributing towards the evolution seen in each of these periods.

METHODS

We analyzed data on the Northeast Region obtained from the Brazilian DHS surveys carried out between May and September 1986 (DHS 1986), February and July 1996 (DHS 1996), and between November 2006 and April 2007 (DHS 2006). The DHS are probabilistic household surveys that are part of an international research initiative aimed at obtaining country-wide information on fertility, infant and maternal mortality, contraception, and woman and child health.

The three surveys used similar complex sampling procedures involving regional stratification of census tracts (one stratum of which was the Northeast Region), random selection of clusters of tracts within each stratum, and random selection of households within each tract. In the selected households, all women aged 15-49 years and all of their biological children under five years of age were eligible to participate in the survey.

The total number of children in the Northeast Region aged zero to 59 months was 1,302 in the 1986 DHS, 2,108 in the 1996 DHS, and 950 in the 2006 DHS. The proportion of children in this region that did not undergo anthropometric evaluation (usually for not being home at the time of the interview) in the three surveys was 9.4%, 10.3%, and 7.9%, respectively. Children who were measured and children who were not measured did not differ significantly in terms of family purchasing power and maternal schooling in any of the surveys. In addition to children not measured, we also excluded from the analysis any child whose height, weight, or weight/height values were biologically implausible.

This criterion disqualified less than 1% of measured children in all three surveys. The final sample of children for the Northeast Region with valid values for height (the central anthropometric variable in the present study) was 1,177 children in 1986, 1,872 in 1996, and 870 in 2006. The sample of children with valid height and weight comprised 1,170 children in 1986, 1,845 in 1996, and 862 in 2006.

In the three surveys, weight and length (up to age 23 months) or height (24 months and older) were obtained by pairs of interviewers previously trained and standardized, using scales with 100 g precision and stadiometers with 1mm precision. The remaining data analyzed in present study were obtained using questionnaires adapted from the DHS model.

Temporal variation in risk of childhood undernutrition across the three surveys was determined by comparing prevalence estimates (and their respective 95% confidence intervals) for stunting (height-for-age deficit) and wasting (weight-for-height deficit). Stunting and wasting were defined, respectively, as height more than two standard-deviations below the expected median.
for the child’s age and sex, and weight more than two standard-deviations below the expected median for the child’s height and sex. In both cases, we based our measurements on the World Health Organization’s anthropometric reference curves, built using the distribution of measurements of children in optimal conditions of nutrition.

Variables that could potentially “explain” the temporal variation in risk of undernutrition in the 1986-1996 and 1996-2006 periods were selected based on the United Nations Children’s Fund (UNICEF) causality model for child undernutrition and on the availability of information collected in the three surveys. We considered five determinants of child nutritional status: family purchasing power, maternal schooling, water supply/sewage, health care, and maternal reproductive indicators.

We evaluated family purchasing power using the Classificação Econômica Brasil. This system divides subjects into five classes of decreasing purchasing power (A, B, C, D, and E) based on intervals of the total score attained by the family on a scale where points are attributed to ten items (type and number of assets in the household, characteristics of the home, and years of schooling of the head of household). Scoring for the different items is carried out so as to maximize the correlation between total score and monthly income. In the 1996 DHS, information on one item in the scale was absent (presence of freezer in the household), and was therefore imputed based on a regression model of the other items over the missing one (model based on the DHS 2006 database). In the 1986 DHS, given that information was available on only six of the ten classification items, we defined new intervals for the scale to characterize the five classes, maintaining proportionality with the original ten-item scale. To make adjacent surveys comparable, the classification of purchasing power in the 1996 DHS was done according to the original intervals of the ten-item score of the Classificação Econômica Brasil and according to intervals derived from the six-item score. Given the low proportion of children in the upper three purchasing power classes (A, B, and C) in the three surveys, we divided subjects into only three classes of purchasing power: classes A, B, and C grouped into a single category, class D, and class E.

Schooling of the mothers of children from the three surveys was classified into intervals of completed years of education. The analysis of water supply and sewage coverage considered the access of the household to the public water supply and public sewage services. For health service coverage, we considered antenatal care (at least one appointment, since no information on number of appointments was available in the 1986 DHS) and hospital delivery. Maternal reproductive indicators evaluated included birth order, birth spacing, and mother’s age at birth. Due to the high correlation between the investigated components of both services coverage and maternal reproductive indicators, we chose to create unique categorical variables combining the information obtained for each component. For example, water supply and sewage coverage were described by a single variable composed of three categories: access to water and sewage services, access to one of these two services, and no access to any of these services.

Since prevalence of wasting was very low in all three surveys, the analysis of factors influencing the temporal variation in prevalence of child undernutrition in the two periods was restricted to prevalence of stunting (from now on referred to as prevalence of undernutrition). This analysis was conducted in four stages. In the first stage, we analyzed the evolution in the distribution of each of the five potential determinants of nutritional status in the 1986-1996 and 1996-2006 periods. We used tests based on the chi-squared distribution to determine the statistical significance of temporal variation in each period.

In the second stage, we examined, at the beginning of each period, the association between determinants of nutritional status and prevalence of undernutrition. This analysis was carried out using Poisson multiple regression models applied to the 1986 and 1996 surveys. These models, which we refer to as the 1986 and 1996 models, produced adjusted relative risks of undernutrition that estimated, at the beginning of each period, the intensity and direction of the independent association between each explanatory variable in the model (determinant of nutritional status) and the presence of child undernutrition. The statistical significance of the association was evaluated using the regression coefficient associated with the explanatory variable (expressed as a continuous variable).

In the third stage, we estimated the effect that changes in the distribution of the five determinants may have had on the evolution of prevalence of undernutrition in each of the periods. This effect was estimated for the 1986-1996 period by comparing mean predicted values for the probability of undernutrition arrived to by applying the 1986 risk model to the DHS 1986 dataset itself and subsequently to the DHS 1996 dataset. Analogously, we estimated the effect of changes occurred in the 1996-2006 period by applying the 1996 model sequentially to the DHS 1996 and DHS 2006 datasets.

In the fourth stage, we attempted to estimate, in each period, the effect which isolated evolution in each of the determinants would have had on prevalence of

---

undernutrition. This effect was estimated by calculating the “generalized attributable fraction.” This measure corresponds to the proportional reduction in a given disease that would result from a change in the distribution of one or more of its determinants. The generalized attributable fraction is essentially an extension of the “population attributable fraction” applicable to situations in which there are changes in the distribution of risk factors, and not necessarily their elimination. Given that the studied determinants are highly correlated among themselves, we used adjusted estimators of the generalized attributable fraction.

The following equation below estimates the generalized attributable fraction (Gaf) associated with a change in the distribution of each of the determinants of nutritional status under scrutiny:

$$Gaf = \frac{\left(\sum_{i=1}^{N} Ai \times RRi\right) - \left(\sum_{i=1}^{N} Bi \times RRi\right)}{\left(\sum_{i=1}^{N} Ai \times RRi\right)}$$

where RRi represents the relative adjusted risk estimated for each ith possible combination of the categories of the five determinants of nutritional status at the beginning of the period of interest (1986 or 1996), and Ai and Bi represent the proportion of children in each ith combination, respectively, at the beginning of the period and in a hypothetical distribution defined by fixing the marginal distribution of the determinant of interest as observed at the end of the period (1996 or 2006) and the marginal distribution of the other determinants as observed at the beginning of the period. It should be noted that there are 324 possible combinations (N) among the categories of the five determinants investigated.

Thus calculated, the generalized attributable fraction estimates the effect of temporal variation in each of the determinants on prevalence of undernutrition. However, the estimated effects for each determinant are not additive, tending to add up to more than the joint effect previously calculated for the changes observed simultaneously on the five determinants. This scenario, which prevents the perfect decomposition of the set of changes into the five determinants, results from the artificial assumption that a change in a given determinant precedes the changes in the other determinants. In any case, the estimate obtained for each of the determinants is indicative of its relative importance in the evolution of undernutrition in each period.

Statistical analysis, carried out using Stata software, version 10, took into account the individual weighting factors of each survey and the effect of the complex sampling design on the standard error of the estimates.

RESULTS

Table 1 presents estimates of the prevalence of anthropometric deficit in the under-five population of Northeastern Brazil in 1986, 1996, and 2006. Prevalence of wasting did not vary significantly across the three surveys, remaining at around 2-3%, which is compatible with the expected level for a healthy, well-nourished population. Prevalence of stunting, which was high in 1986 (33.9%), fell in 1996 (22.2%) and even further in 2006 (5.9%), a relative reduction of 34.3% in the first period and 73.4% in the second.

Table 2 presents the frequency of determinants of childhood nutritional status in each of the three periods. Though evolution of all five determinants investigated was favorable and significant in the two periods, temporal variations tended to be more marked in the most recent period, especially those relating to family purchasing power and maternal schooling. Regarding family purchasing power, evolution was only marginally favorable between 1986 and 1996, but was exceptionally favorable between 1996 and 2006. Children in the lowest purchasing power class (class E) represented more than half of the child population in 1996, but only one-quarter of this population in 2006. Despite improvements in water supply and sewage, in 2006, only slightly over a quarter of the child population in the Northeast lived in homes with access to the public water supply and sewage services.

Table 3 presents the results of multiple regression models for the association, at the beginning of each period (1986 or 1996), between determinants of nutritional status and occurrence of undernutrition. Significant associations, after adjustment for the remaining factors, were found for all determinants in 1996 and for all but health services in 1986.

Table 4 describes the joint effect on undernutrition of the favorable changes in the five determinants in each

period. These estimates were obtained based on predictions regarding the mean probability of undernutrition in which the 1986 risk model is applied in succession to the distribution of determinants in 1986 and 1996, and the 1996 risk model is applied in succession to these distributions in 1996 and 2006.

As expected, the predicted mean probability using the risk model and distribution from a same year was very similar to the actual prevalence of undernutrition in that year. The small differences that exist are the result of the exclusion of children without valid data for all determinants.

Replacing the distribution of determinants observed at the beginning of each period with that of the end of the period “explains” a substantial part of the reduction in prevalence of undernutrition in both periods. For 1986-1996, the mean probability of undernutrition would decline from 33.8% to 27.3%, a relative decrease of roughly 20%, equivalent to a little over half of the decline actually registered in the period (34.5%). For 1996-2006, the mean probability of undernutrition would fall from 22.2% to 11.8%, a relative decrease of almost 50%, or almost two-thirds of the decline actually registered in the period (73.4%). In short, the simultaneous favorable evolution of family purchasing power, maternal schooling, water supply and sewage, health care, and maternal reproductive indicators would account for a little over half of the decline in prevalence of child undernutrition between 1986 and 1996, and almost two-thirds of this decline between 1996 and 2006.

The Figure displays estimates for the decline in prevalence of undernutrition expected for each period based on the risk model and distribution from each period.

*All studied variables varied significantly in relation to the previous period (p<0.01).

Very unfavorable indicators: birth spacing < 24 months and birth order ≥ 5 or mother’s age at birth < 18 years; unfavorable indicators: any one of the above conditions; favorable indicators: order of birth < 5; birth spacing ≥ 24 months, and mothers age at birth > 18 years.
on the favorable evolution of each of the determinants investigated, maintaining the distribution of the remaining determinants at the levels observed at the beginning of the period. As explained previously, these estimates, obtained by calculating the generalized attributable fraction, are indicative of the relative importance of each determinant on the temporal variation in prevalence of child undernutrition in the period.

Improvements in maternal schooling and in water supply and sewage coverage seem to have driven most of the decline in undernutrition in the 1986-1996 period, each accounting for a relative reduction of approximately 10% in prevalence of undernutrition. Improvement in maternal reproductive indicators occupies an intermediate position, and increases in family purchasing power were only marginally relevant. The effect of the favorable evolution of health care coverage was not estimated for the earlier period since no association was detected between this factor and undernutrition.

The most relevant factor for the decline in undernutrition between 1996 and 2006 was the improvement in family purchasing power. This factor alone accounts for a 24.9% decrease in prevalence of undernutrition. Family purchasing power is followed, in order of decreasing contribution, by improvements in maternal schooling, water supply and sewage, reproductive antecedents, and health care.

**DISCUSSION**

Our analysis of data from three household surveys spanning a period of 20 years showed a rapid improvement in

* Adjusted for all variables in the table.

*Very unfavorable indicators: birth spacing < 24 months and birth order ≥ 5 or mother's age at birth < 18 years; unfavorable indicators: any one of the above conditions; favorable indicators: order of birth < 5; birth spacing ≥ 24 months, and mothers age at birth > 18 years.

Simultaneous improvements in family purchasing power, maternal schooling, water supply, sewage and health care services coverage, and maternal reproductive indicators could account for a little over half the decline in prevalence of child undernutrition in 1986-1996, and for almost two thirds of this decline in 1996-2006. Improvements in maternal schooling and sanitation coverage were especially important for the decline seen in the first period, whereas increased purchasing power and, again, improved maternal schooling were decisive in the second period. The acceleration of the decline between the first and second periods was consistent with the increased intensity of improvements in maternal schooling, water supply/sewage, health care, maternal reproductive indicators, and, especially, the exceptional increase in family purchasing power, seen only in the more recent period.

The probabilistic character of the three surveys, their comparability with regard to the collection and analysis of anthropometric data, and the use of inclusive indicators for evaluating nutritional status (stunting and wasting), strengthen the internal and external validity of our present results on the evolution of child undernutrition. Furthermore, independent health and nutrition surveys carried out in the states of Pernambuco and Alagoas in periods close to 1996 and 2006 have documented similar reductions in prevalence of stunting to those reported in the present study for the entire underfive population of the Brazilian Northeast. The Chamada Nutricional survey, conducted in 2005 in the 1,133 municipalities of the Brazilian semiarid, most of which are located in the Northeast Region, estimated the prevalence of stunting at 6.6%, which is close to the 5.9% prevalence estimated for the Northeast Region in the 2006 DHS.

The recent evolution of the prevalence of growth deficits in the Brazilian Northeast indicates that the United Nations Millennium Development Goal for child undernutrition (50% reduction between 1990 and 2015) will be widely exceeded, as previously shown for the child population of Brazil as a whole.

Regarding the causes behind the improvements in nutrition in each of the periods, our results should be understood as an approximation to reality, be it due to the analytical challenges associated with this estimation or to the limited availability of information on determinants of nutritional status in the three surveys. One of these limitations is the relative weakness of the indicator used to evaluate health service availability. This indicator was restricted to antenatal care and hospital delivery, and therefore did not include any direct indicator of the care provided to children in their first five years of life. We originally intended to include in this indicator the extent to which children were compliant with the immunization schedule followed by the primary health care network. However, this proved unviable in light of the inconsistency of the information contained in the 2006 DHS. The number of antenatal care appointments, which could provide a better estimate of the quality of health care provided, was only available for the 1996 and 2006 surveys. Thus, though access to antenatal care is likely to be correlated to a certain degree with access to other health care interventions, it is possible that part of the “impact” of global improvements in health service coverage was not captured by our data.

*1986, 1996, and 2006 refer to the survey year based on which the models were constructed and/or from which distributions were extracted. Explanatory variables in the 1986 model: family purchasing power, maternal schooling, water supply/sewage coverage, and maternal reproductive variables; the same variables plus health service coverage are included in the 1996 model.
Decline in undernutrition in Northeastern Brazil Lima ALL et al

In a previous study of the causes of the decline in under-five nutrition in Brazil, we identified increases in maternal schooling, family purchasing power, health care, and sanitation, in this order, as the most relevant factors contributing to the decline in the national prevalence of undernutrition between 1996 and 2006. The lack of detailed information on these variables in the national surveys carried out in 1975 and 1989 prevented us from analyzing the determinants of child undernutrition prior to 1996, which we accomplished for the first time in the present study.

The marked reduction in the frequency of Northeastern children in class E between 1996 and 2006 is consistent with estimates of family income based on the 2001 and 2007 Brazilian Household Budget Surveys. These estimates indicate that there was in the Northeast a substantial displacement of the population from the lowest to the intermediate income stratum. Experts on the subject tend to agree that recent improvements in income distribution and reduction of poverty in Brazil are a consequence of the recovery of economic growth and the consequent reduction in unemployment, higher-than-inflation raises in the minimum wage, and of a vigorous expansion of income transfer programs.

The rapid improvement in maternal schooling in the Northeast Region between 1996 and 2006 reflects the virtual universalization of access to elementary schooling and improvements in some of its performance indicators seen across the entire country throughout the 1990’s. It is worth noting that most mothers of children surveyed in 2007 either were in elementary school or were old enough to be in elementary school in the 1990’s, whereas the reference period for elementary schooling was the 1980’s for mothers studied in 1996 and the 1970’s for those studied in 1986.

The virtual universalization of antenatal care in the Northeast seen between 1996 and 2006 coincides with the expansion, in the entire country, of the Programa de Saúde da Família (PSF – Family Health Program), a program that emphasizes preventative and educational measures and the promotion of equity in health service supply. In 1998, 1,230 PSF teams were operating in 21.9% of Northeastern municipalities, covering roughly four million people, or 9.3% of the population of Northeastern Brazil. In 2006, 11,150 PSF teams were operating in 98% of Northeastern municipalities, covering 35 million people, or 67.2% of the population of the Northeast Region.

Figure. Relative reduction (%) in prevalence of stunting (height-for-age deficit) attributable to the evolution of selected factors in two periods. Northeastern Brazil; 1986-1996 and 1996-2006.

---

The modest improvement in water supply and sewage is a result of a slow expansion in the coverage of these public services. Between 2001 and 2007, the proportion of homes in the Northeast connected to the sewage network increased from 22.0% to 29.7%. In the same period, coverage of the water supply network increased from 69.2% to 75.7%. Brazilian social scientists have drawn attention to the lower visibility and political attractiveness of basic sanitation, highlighting the need to raise the priority of this issue in the Brazilian public policy agenda.\textsuperscript{10}

The progressive reduction in the frequency of unfavorable maternal reproductive indicators is consistent with the also progressive reduction in fertility in the Brazilian Northeast, from 5.2 children per woman in 1986 to 3.1 in 1996 and 1.75 in 2006.\textsuperscript{b,c,d} Moreover, the fertility rate in the Northeast in 2006 is no longer higher than the national average (1.77 children per woman),\textsuperscript{1} as is the case with prevalence of child undernutrition.\textsuperscript{8}

If the annual rate of decline in prevalence of stunting – over 7% – is maintained, the proportion of children in the Northeast Region with height more than two standard deviations below the expected median for their age will reach 2.3% in less than ten years, which would mean equaling the expected proportion (genetically) of low-stature children under optimal conditions of diet, health, and nutrition.\textsuperscript{16} However, achieving this goal will require the maintenance of initiatives that have favored an increase in purchasing power among the poor in the Brazilian Northeast and – no less importantly – ensuring public investments aiming at completing the process of universalization of access to essential education, health, and water supply and sewage services.
