Smoking Prevalence in Cienfuegos City, Cuba

Mikhail Benet MD PhD, Alfredo Espinosa MD PhD, Alain Morejón MD MS, Emiliano Diez MD MS, Orlando Landrove MD MS, Pedro O. Ordúñez MD PhD

INTRODUCTION

Over the last 40 years, high smoking prevalence has been reported throughout Cuba, including in Cienfuegos city in the central part of the island.

OBJECTIVE

METHODS

A descriptive cross-sectional study was conducted in Cienfuegos city in the context of CARMEN (Collaborative Action for Risk Factor Prevention & Effective Management of Non-communicable Diseases), a PAHO multi-country initiative for a multidimensional approach to chronic non-communicable diseases. Participants totaled 2193 (aged 15–74 years), randomly selected through complex probabilistic three-stage sampling. Variables examined in relation to smoking included age, sex, skin color, civil status and educational level.

RESULTS

Approximately 25% of those surveyed were smokers (30.3% of men and 21.0% of women). For men, prevalence was highest in the groups aged 25–34 and 55–64 years; for women, in the group aged 45–54 years. Concerning skin color, smoking rates were higher among black and mestizo persons (29.5%); and concerning civil status, higher among those who were separated, widowed or divorced (30.0%). Smoking prevalence fell with higher educational level, in keeping with that trend, the university-educated group had the lowest prevalence (16.2%).

CONCLUSIONS

Although one in four Cienfuegos residents aged ≥15 years smoked in 2010–2011, prevalence there is lower than in previous surveys. Knowledge of differences observed in age, sex, skin color, civil status and educational level can be useful for planning future smoking prevention and control actions.

KEYWORDS

Tobacco, smoking, prevalence, health surveys, risk factor surveillance, Cuba
number planned. Specialists from the local branch of the Provincial Statistics Office participated in all phases of the process. Details of the sampling methods have been published previously.[13]

Data were collected using the CARMEN-recommended questionnaire.[9] The interviewers, health professionals trained for this task, visited households selected for the sample, surveying a total of 2193 individuals.

Variables examined included: age group, sex, self-declared skin color (white; mestizo or black), educational level completed (primary: first to sixth grade; middle school: seventh to ninth grade; high school or middle-level technical training: 10th to 12th grade; university: beyond 12th grade), and civil status (single; married or cohabitating; and separated, widowed or divorced).

Data recorded from questionnaires were first entered into a Microsoft Access database programmed for the study and transferred to the SPSS Complex Samples-15 model for statistical analysis and calculation of estimates with 95% confidence intervals. The sample was weighted to population subgroup distribution in Cienfuegos city as of study initiation. Rates were adjusted for age and sex. Results were presented in tables and figures, by relative frequencies with their confidence intervals. In some cases, the Pearson chi-square test of independence was applied to compare results among groups. The statistical significance level was set at 0.05.

The Medical University of Cienfuegos research ethics committee approved the initial project and each theme analyzed in the study. All survey participants gave prior written consent.

RESULTS

Of the desired sample of 2400 participants, 2193 (91.4%) were surveyed. Most persons surveyed were in the subgroups aged 35–44 and 45–54 years, women (57.7%), white (70%) and married or cohabiting (59.4%) (Table 1).

Approximately 25% of the population surveyed smoked, with higher prevalence in men (30.3%). Prevalence in men was highest in those aged 25–34 and 55–64; in women, it was highest in those aged 45–54 years (Table 2).

Higher rates were observed in mestizo or black persons (29.5%), and this held true for men (35.7%) as well as women (25.1%). Prevalence was higher in the separated, widowed or divorced than in those with other civil status. Finally, as educational level rose, smoking prevalence fell, resulting in the lowest rates among university graduates (16.2%) (Table 3).

DISCUSSION

First the bad news: this study reconfirms that 1 in 4 Cienfuegos city residents aged ≥15 years smokes, still slightly higher than the national prevalence from preliminary data.[11] The good news is that smoking prevalence has been steadily declining over the last two decades (although perhaps not as much as was hoped). Smoking prevalence has been closely monitored in Cienfuegos city since the early 1990s (33% in 1991–1992, 31% in 2001–2002 and 25% in 2010–2011),[8,9] so it can be confirmed that Cuba’s public health goal for 2010 of reducing smoking prevalence to 26% has been achieved in Cienfuegos.[2]
Smoking declines have been more marked over the last ten years (i.e., between the 2001–2002 and 2010–2011 surveys). These results contrast with statistics from the 1990s, when smoking prevalence remained almost constant (from 1991–1992 to 2001–2002), in the midst of Cuba’s serious economic crisis, despite multiple shortfalls and the high cost of tobacco products, as well as public education campaigns.[2]

Strategies to combat the smoking epidemic include health information and education, appropriate legislation, and availability of smoking cessation services. Activities have been conducted in all three of these areas at national, provincial and city levels, although much remains to be done.[2,14,15]

One explanation for the more encouraging recent results could be that long-term effects of previous interventions are now being felt at both community and individual levels,[14,16] especially in reducing smoking among younger age groups. However, it is important to remain vigilant. Two main objectives of the antismoking campaign are: reduce the number of young people who start smoking and among those who do pick up the habit, delay onset as long as possible; and reduce the number of current smokers by providing counseling services to help them quit.[15]

It is noteworthy that although men smoke more than women, the steepest decline in smoking has been among men, where prevalence dropped from 43% in 1991–1992 to 39% in 2001–2002 and then to 30% in 2010–2011. Meanwhile, statistics for women smokers have held fairly steady (23% in 1991–1992, 23% in 2001–2002 and 21% in 2010–2011), a fact which should be underscored when prevention/cessation activities are designed for women.[8,17]

The issue of women and smoking has been widely addressed in all three of these areas at national, provincial and city levels, particularly in the language and forms of expression used in these campaigns.

The higher prevalence found among mestizo and black Cienfuegos residents, already reported as of 1991–1992,[8] could be related to socioeconomic conditions, educational level, or other factors not part of this study. Research on hypertension in Cienfuegos city concluded that there were no differences among white, black and mestizo residents in terms of availability of and access to health services, but there were differences in terms of adherence to therapy, which could also be influenced by socioeconomic and educational factors.[12,22] Our results thus alert us to the need to further investigate associations of skin color, socioeconomic conditions, educational level and other factors, to determine how these may relate to smoking, in order to better target actions to further reduce smoking in these populations.

Another interesting result has been the higher prevalence of smokers among separated, widowed or divorced persons, as was observed in the 1991–1992 survey.[8] Differences by civil status cannot be interpreted in isolation, since other variables such as sex, age, educational level, drinking prevalence and socioeconomic status can also influence results. This does not mean that this should not be considered as a factor, particularly because it has been a consistent result over time, at least in Cienfuegos city.[8]

The higher smoking prevalence among less educated participants (34%), twice as high as for university-educated persons (16%), although predicted, underscores the importance of education in curbing risk behaviors. In 1991–1992, smoking prevalence in non–university-educated individuals (37%) was higher than among university graduates (25%).[8] The good news is that higher educational levels achieved over the last 20 years appear to have effectively acted as a protective factor. In the 2010–2011 CARMEN survey 18.1% of the adult Cienfuegos population was university educated,[9] up from 9.1% in 1991 (unpublished data). In any case, the educational level of the smoking population is an important factor to consider in designing and organizing antismoking media campaigns, as well as in the language and forms of expression used in these campaigns.

CONCLUSIONS

Smoking prevalence in Cienfuegos city was markedly lower in 2010–2011 than in previous surveys. Knowledge of differences in smoking prevalence by age group, sex, skin color, civil status and educational level can be useful for instituting new actions in public health and tobacco control in this Cuban municipality.
